20. ABSTRACT (Continue on reverse side if necessary and identify by block number) Ionospheric scintillation fading on a UHF earth-to-satellite communication link has a strong dependence on season, time-of-day, and geographic location. In the equatorial region $\pm 20^\circ$ from the magnetic equator, 20 to 30 dB fades can be expected 1 to 2 hours after sunset during the equinox period. Airborne terminals may experience fade rates as fast as 1 fade per second to as slow as 1 fade in 90 seconds, depending on the direction of flight. The amplitude fading follows a power law distribution with a rate of F-2 to F-4 depending on fade rate.

SECURITY CLASSIFICATION OF THIS PAGE(When Data Entered)

In the polar region an airborne terminal may experience ionospheric scintillation more often than near the equator but usually with less amplitude. Polar fading of 10 dB or less may occur 10 to 30% of the time.

In the mid latitudes occasional random ionospheric scintillation may occur, but the fade depth and occurrence are so small as to pose only a minor annoyance to an airborne satellite communication system.

## FOREWORD

This report describes an in-house effort conducted in the Systems Avionics Division, Avionics Communication Branch (AFAL/AAD), Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio, under Project No. 1227, "Terminal Technology," Task No. 122703 "Test Efforts," Work Unit 12270313 "SATCOM Flight Test Effort." The work reported herein was performed during the period January 1976 through May 1978.

The test effort was a cooperative venture between a number of Government agencies with the support of several contractors. The support of the following individuals and agencies was instrumental in the successful accomplishment of this effort:

AFAL: T. A. Grizinski, R. L. Swanson, J. J. Foshee, R. C. Beach, W. O. Fischbach, P. Heidkamp, G. J. Johnson

4950th Test Wing: Capt. R. Ewart, T/Sgt J. Cary, P. Frank, S. Wilson, R. Chin

Air Force Geophysics Laboratory (AFGL): J. Aarons, H. Whitney, J. Mullen, J. Buchau, Capt. E. Weber

Naval Ocean Systems Center (NOSC): R. Hopkins

ESL Inc: Dr. C. Prettie

Sylvania Corp.: K. Dusenbury

## SECTION I

## INTRODUCTION

The objective of this report is to describe the limitations which ionospheric irregularities impose upon aircraft-to-satellite communication systems as depicted in Figure 1. The effect of ionospheric scintillation on ground-to-satellite communications has been extensively reported [Aarons, et al (References 1,2,3,4,5), Paulson and Hopkins (Reference 6), Crane (Reference 7), Rino, et al Reference 8]. While the same ionospheric irregularities are causing the communication problem for both the ground and aircraft communication terminal, the resultant characteristics of the airborne fading differ from the ground fading characteristics. Therefore, the techniques which might be employed to alleviate the ionospheric scintillation fading effects will differ for the airborne situation.

Ionospheric scintillation fading occurs as a result of sharp ion or electron gradients which occur in the ionosphere. These sharp gradients are caused by the ionospheric irregularities which tend to refract or focus the radio waves as they pass from the earth's surface to the satellite. While the irregularities can occur anywhere over the earth's surface, the probability of occurrence is more likely in the polar and equatorial region as depicted by Aarons, et al (Reference 3) in Figure 2. In the polar regions the occurrence is greatest near the auroral oval. In the equatorial region scintillation is predominantly a night-time effect, usually occurring one to two hours after local sunset and lasting past local midnight. In the midlatitudes scintillation seldom occurs and usually is of short duration when it does occur.

The development of ionospheric irregularities leading to scintillation is controlled by the earth's magnetic field. In the equatorial region the ionospheric irregularities are magnetic field aligned and

Figure 1. Air-To-Satellite-To-Ground Communication Path

DEPTH OF SCINTILLATION FADING ( PROPORTIONAL TO  
DENSITY OF CROSSHATCHING )

Figure 2. Geographic Distribution of Ionospheric Scintillation  
Fading (From Aarons et al Reference 3)

extend  $\pm 15^\circ$  in latitude around the magnetic equator. In the high latitudes the magnetic field controls the location of the particle precipitation responsible for the formation of the irregularities. The scintillation regions are organized by L-shells or invariant geomagnetic latitudes as shown in Figure 3, Crane (Reference 7). While the exact cause of the ionospheric irregularities is not completely understood, the resultant effects are clearly identifiable. The irregularities tend to form along the magnetic field lines between a 200 to 1000 kilometer altitude. Instabilities in the ionosphere triggered by some natural phenomena tend to expand rapidly, forming high electron concentration or electron depletion regions which produce the observed scintillation. These irregularities, once formed, tend to cause a diffraction pattern effect on the earth's surface. The result is an irregular sequence of enhancements and null regions, Figure 4. The ionospheric irregularities are not stationary but tend to move due to electric field and/or neutral ionospheric winds and change in size and shape with time. The effect on earth-to-satellite communications is a signal amplitude and phase scintillation which is frequency dependent. The frequency dependence of the fading appears to change with the fading intensity. It varies over a range of  $f^{-1}$  to  $f^{-3}$ . Several data points are summarized in Figure 5.

Figure 5. Frequency Dependence of Ionospheric Scintillation Fading

## SECTION II

## EQUATORIAL SCINTILLATION CHARACTERISTICS

Equatorial ionospheric scintillation is predominantly a night-time event, occurring usually one to two hours after local sunset. The occurrence appears to be the result of electron density irregularities which develop in the 200 to 300 kilometer altitude and which are amplified and rise rapidly to the 700 to 1000 kilometer altitude, forming the bubble and plume configuration noted by McClure (Reference 9). The individual irregularities/structures appear to be well defined, field aligned electron density depletion regions with ion or electron densities differing by one to two orders of magnitude from the surrounding region. They seem to define large scale volumes containing irregularities of various scale sizes. Each irregularity structure, once formed, tends to drift in a easterly direction for a period of hours, usually dissipating around local midnight. During the early development of the large structures and the imbedded small scale irregularities very rapid amplitude and phase scintillation is noted due either to the very turbulent vertical motion during the irregularity formation or to very intense irregularities. Later in their lifetime the irregularities appear to change more slowly. The scintillation noted on the earth is then due to the irregularities drifting over and past the observer.

The probability of occurrence of scintillation fading is not uniform along the equator. There appears to be both a time of year dependence and a longitude dependence. Measurements made by Basu, et al (Reference 10) during November-December showed a peak probability in the 0 to 90° west quadrant of the equatorial region, Figure 6. Measurements reported by Nichols (Reference 11) showed a minimum in Nov-Dec at 168°E 10°N and a peak in the local summer, Figure 7. Contour plots of the probability of occurrence versus time of day and month from Aarons, et al (Reference 4) are shown in Figure 8. This figure shows a very definite peaking of the scintillation probability during the vernal

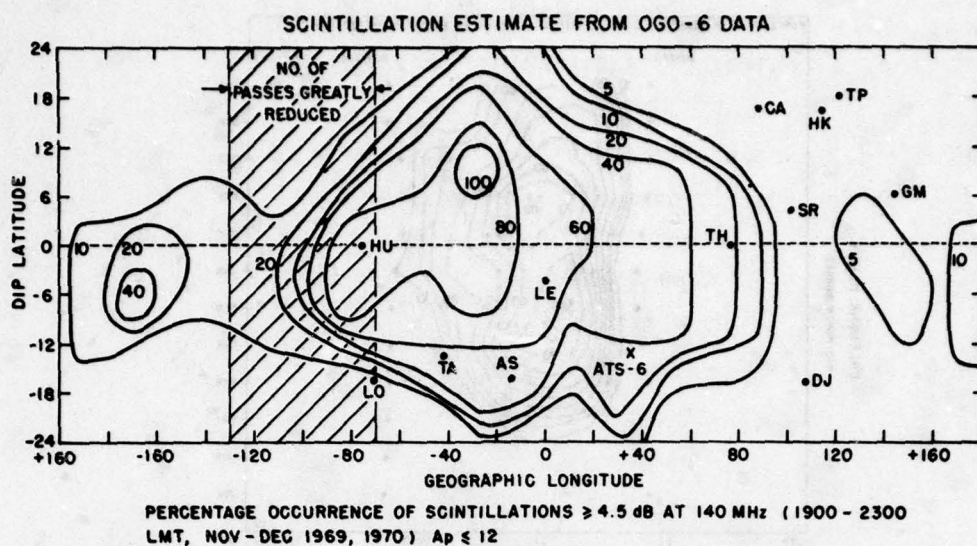

Figure 6. Model of Estimated Scintillation  $\geq 4.5$  dB Over the Equatorial Region (From BASU et al Reference 10)

Figure 8. Monthly Contour Plot Showing the Percentage Occurrence of  $SI \geq 60$  ( $S_4 \geq 0.3$ ) at Huancayo, Peru (From Aarons Reference 4)

and autumnal equinox periods. The nightly occurrence of scintillation at Guam was shown by Johnson (Reference 12), Figure 9. During the Fall of 1976 scintillation occurrence data was taken by Barkham (Reference 13) in Australia, Figures 10 and 11; Paulson and Hopkins (Reference 6) in Guam, Figure 12; and Whitney, et al (Reference 14), Peru, Figure 13. While little scintillation was noted in Australia and Guam during the mid to late October period, extensive scintillation was recorded in Peru. During a test in March 1977 scintillation was noted every night in Peru, Figure 14. Paulson and Hopkins (Reference 6) have observed an apparent correlation between the sun spot number and the occurrence of scintillation in the Guam area, Figure 15. That data predicts an increased activity of equatorial scintillation with the upcoming sun spot maximum in 1981.

Figure 15. Dependence of Scintillation on Solar Activity (From Paulson and Hopkins Reference 6)

The individual equatorial irregularity structures are from 50 to 200 kilometers wide in an east-west direction with a north-south extent of 2000 to 3000 kilometers, Weber et al (Reference 15). The irregularity structures are aligned along the magnetic field lines and appear to be relatively symmetrical with respect to the magnetic equator. While the individual irregularities within the large structures vary in size from meters to tens of kilometers, the irregularities which cause VHF and UHF scintillation have a scale size of approximately a kilometer in width. These individual irregularities tend to be elongated in a north-south direction along the north-south axis, having a length of tens of kilometers as compared with their approximately one kilometer width. Correlation of the fading on spaced ground antennas indicates that the velocity of the ionospheric irregularity drift is from 50 to 200 meters per second, generally in a westernly to easternly direction.

An extensive series of airborne and ground measurements were taken in Peru during 1976 and 1977, Whitney, et al (Reference 14). The airborne scintillation fading experienced from a 250 MHz satellite signal varied from extremely fast to extremely slow, as shown in Figure 16. The signal amplitude plots show peak-to-null fading of 25 - 35 dB. In order to compare the fading effects occurring at the ground station with those observed by the airborne terminal, the flight pattern shown in Figure 17 was adopted. The aircraft flew over the two cooperating ground stations at various aircraft headings. A plot of the scintillation amplitude and fade rate for the airborne terminal is shown in Figure 18. The legend at the bottom of the figure shows the aircraft heading in addition to which ground station it was over. The curves in Figure 18 show a very rapid onset of scintillation with an extremely fast fade rate of 90 fades in a two-minute period. The amplitude of the fading remains high over a considerable portion of the night, but the fade rate varies depending upon aircraft flight direction. Comparison was made of the fade rate experienced on the ground, and that experienced in the aircraft flying over the ground station. The ratio of the airborne-to-ground fade rate is plotted in Figure 19. The solid and dotted

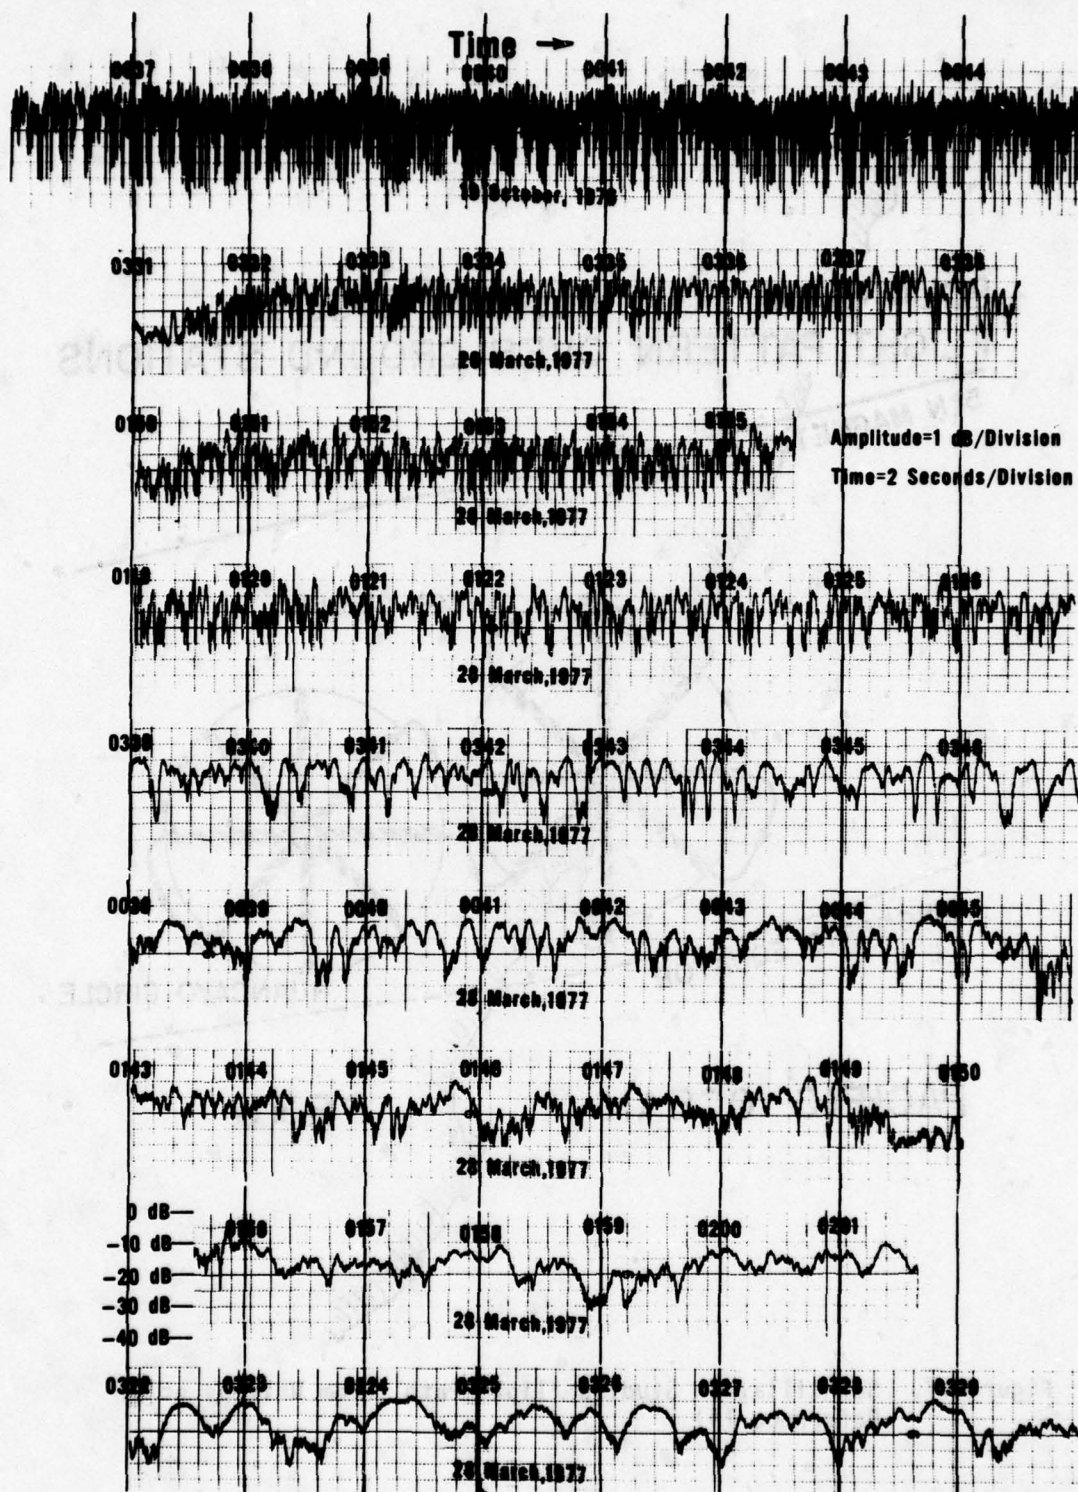

Figure 16. Equatorial UHF Ionospheric Scintillation Fade Variations

Figure 17. Scintillation Studies Flight Path (From Whitney et al Reference 14)

Figure 18. Scintillation Amplitude and Rate: Peru Local Flight

Figure 19. Ratio of Airborne-to-Ground Fade Rate versus Aircraft Flight Direction

curves are the theoretical speed-up factors which would be expected from a constant aircraft velocity as the aircraft flies in different directions. Due to the effect of local winds the actual aircraft velocity over the ground varies with heading. However, the ratio of air-to-ground fading correlates very well with the theoretically predicted fade rate ratio. The data showed that when flying in a westerly direction, fade rates of two to three times faster than the ground fade rate could be experienced on the airborne terminal. When flying in a northeasterly or southeasterly direction, extremely slow fade rates can be experienced. Histograms of the fade amplitude for the various fade rates recorded are shown in Figures 20 through 28. They show roughly the same fade distribution independent of fade rate. The cumulative distribution of a fade amplitude is shown in Figures 29 to 37 for the various rates of fading. Again, these curves indicate that for deep fading the cumulative distribution closely approximates a Rayleigh distribution and is independent of fade rate. However, a Fourier analysis of the amplitude fading data shows a marked change in the frequency components making up the fade structure. For very rapid fading the power spectra tends to decrease as the ratio of the frequencies raised to the -4 power ( $f^{-4}$ ), as shown in Figures 38, 39, and 40. For medium fading the fading decreased at  $f^{-3}$ , as shown in Figures 41 through 43. For very slow fading the power spectra tends to decrease at an  $f^{-2}$  or less, shown in Figures 44 to 46. The auto correlation function decreases to half its initial amplitude in less than two-tenths of a second for the extremely fast fading, Figure 47. That time increases to 7 or 8 seconds as the fade rate decreases, Figures 48 to 55.

The period of the fading (time between successive crossings of the reference level) and the duration of fading (time which the signal remains below the reference level) are important characteristics in the design of any mitigation technique. Plots of the period and duration referenced to 4, 8, and 12 dB below the measured mean signal level are presented in Figures 56 through 65 for fast and slow fading examples.

Figure 64. Fade Duration of Received Signal Amplitude for Slow Fading

Figure 65. Fade Duration of Received Signal Amplitude for Extremely Slow Fading

For the extremely fast fade the reference of 4 dB below the mean showed a fade period always less than 2.5 seconds and less than 0.3 seconds 50% of the time. The duration never exceeded 1.5 seconds and was less than 0.2 seconds 50% of the time.

For the other extreme the very slow fading, the 4 dB reference showed a fade period always less than 60 seconds and never less than 1 second. The duration never exceeded 50 seconds and was less than 0.25 seconds 50% of the time.

Comparison of the fade amplitude, histogram, and cumulative distribution for a ground station at Ancon, Peru with the airborne data as the aircraft flew over the ground station showed some of the inherent differences between airborne and ground data. The ground station data in Figures 66 and 67 shows a narrower range of fade amplitude than that depicted by the airborne data in Figures 20 and 29. While there is no reason why the airborne fading should be any more intense than that experienced on the ground, it is likely that the aircraft sees a wider range of fading conditions since it samples a larger geographical area.

To verify that the airborne fading is identical to the ground fading a test series was run near Guam in 1971. The results of the test, as reported by Johnson (Reference 12), utilized an Air Force aircraft and a Navy ground station on Saipan, Figure 68. The aircraft flew near Saipan such that the ray from the satellite passed through the aircraft to the ground station, Figures 69 and 70. The fading experienced on the ground and in the aircraft is shown in Figure 71. The aircraft was flying in a westerly direction and, therefore, experienced an increased fade rate since it passed through the irregularity structure faster than it drifted over the ground station. By varying the airborne fade rate, it was possible to correlate a seven minute portion of the ground data with a one minute portion of the airborne data,

Figure 71. Comparison of Airborne and Ground Scintillation Fading Data

Figure 72. After finding the correct factor to match the airborne and ground data, a cross correlation was run, Figure 73. A peak correlation of over 0.7 was achieved.

In addition to the amplitude scintillation data, phase scintillation measurements can be of importance in the modeling of the ionospheric effects. Figure 74 (Reference 16) shows a two minute plot of equatorial amplitude fading which was recorded in March 1977. Two very deep fades, approximately 30 dB, occurred during the two minute period along with several 5 to 8 dB enhancements. During most of the amplitude fading the phase scintillation was limited to a fraction of a radian per second. However, during the two very deep fades phase scintillation rates of 10 to 15 radians per second were experienced, Figure 75. Another example of equatorial amplitude and phase scintillation is shown in Figures 76 and 77. In this segment numerous 20 to 30 dB fades occurred during the three minute sample. Again, sharp phase scintillation accompanied the deep amplitude scintillations.

The effect of the fading on the incoming signal power level appears to be sensitive to the type of fading experienced. During a ground test in Peru, data was taken which showed considerable variation in the mean over the three-hour test period. The amplitude and rate of the signal fading are displayed in Figure 78 along with the mean. Little or no change was noted in the mean at the onset of scintillation fading at 20:16 Local(L). At 2100(L) the rate of fading decreased and the amplitude dropped. At that time the mean decreased approximately 3 dB. The fading changed again around 2145(L) to a higher rate and amplitude. The mean responded by increasing almost 5 dB.

The  $S_4$  Index shows the onset of fading and the change of fading type around 2100(L) and 2145(L). For the most part the  $S_4$  Index indicated intense or saturated fading, Figure 78.

Figure 78. Comparison of Equatorial Scintillation Fading Parameters

The auto correlation function provides a mirror of the fade rate. Changes in the fading characteristics such as the fast fading from 2145 to 2240(L) are evident in the plot of the time at which the auto correlation function drops to half its value, Figure 78.

Spaced antennas on the ground have been used to measure the direction and velocity of the ionospheric irregularity's drift. Paulson and Hopkins (Reference 6) have shown very high correlation over distances up to 1000 meters. Data taken by Whitney, et al (Reference 14) at Ancon, Peru showed that the cross correlation between spaced antennas varied as a function of time. Early in the night poor correlation was often experienced, probably either to vertical motion of the ionospheric irregularities or very intense irregularities. Later in the evening high correlation was usually experienced as the already formed irregularities drifted across the two antennas.

While 25 to 35 dB fades occur regularly in the UHF frequency range, the fading at SHF (7.5 GHz) seldom exceeds 1 dB. Simultaneous UHF and SHF scintillation data taken at Ascension Island by Johnson et al (Reference 17) showed large UHF scintillation fading accompanied by approximately 1 dB of SHF scintillation fading, Figure 79. The SHF curve showed a periodic 2 dB cyclical signal variation occurring at a 1 cycle per second rate due to satellite antenna wobble. Superimposed upon the envelope over this curve was a slowly varying 1 dB scintillation fade.

## SECTION III

## POLAR SCINTILLATION CHARACTERISTICS

The F region ionosphere in the Polar area tends to be more complicated and more difficult to quantify than the midlatitude or equatorial region, as noted by Aarons (Reference 2). In this region small scale (1 to 10 kilometer) field aligned irregularities cause ionospheric scintillation fading on aircraft-to-satellite communication links. In general, the fading is still confined to the VHF and UHF region with little effect noted at SHF. In a model developed by Aarons, et al (Reference 5) a frequency dependence of the fade depth is  $F^{-1.9}$  for the Polar region. As a result of observations at a number of Polar sites, Aarons has developed an empirical model showing the probability of fading versus time of day for each month of the year. The other variables in the model are the solar flux and the magnetic index, Kp. The plots by Aarons et al (Reference 5) show the probability of fading occurrence to be low in the winter months, Figure 80, and peaking up during the summer months, Figure 81. These curves still indicate a diurnal variation due to the movement of the auroral oval. These figures support the conclusion that fading can be expected to occur more often in the Polar region than in the equatorial region, but it is expected to be of smaller amplitude than that experienced in the equatorial region.

During a series of flights in the Polar region, data was taken on percentage occurrence of scintillation by Aarons, et al (Reference 3). In that report five regions, or regimes, (Figure 82) were defined with Regime #1 being the ionosphere totally south of the auroral oval; Regime #2 being that area in which the ray passes through both the ionosphere south of the oval and part of the auroral oval, Regime #3 being where it is totally in the auroral oval, Regime #4 being where it is partially in the auroral oval and partially in the polar cap; and Regime #5 being where it is totally in the polar cap. Table I (Reference 3) and Figure 83 show the probability of occurrence of various depth fading in the

various ionospheric regimes. It is interesting to note that while the probability of occurrence of fading is high, the fade depths were relatively low, usually below 10 dB. This is also shown in Figure 84 where the cumulative distribution of scintillation fading for Goose Bay is summarized.

During a series of flights between Norway and Alaska in June 1977, scintillation was observed for approximately 40% of the flight path as shown by Johnson (Reference 18), Figure 85. During a series of flights in the Greenland area during January 1977, scintillation was experienced less than 10% of the time as shown by Johnson (Reference 19), Figure 86. The type of fading which was observed ranged from a rather fast, noise like fading (16 June) to a rather slow fade (15 Aug), shown in Figure 87. Histograms of the fading amplitude and cumulative distribution functions for these two fade samples show considerable difference in the fade structure as can be seen by Figures 88 through 91. Likewise, the auto correlation, fade period, and fade duration curves vary for these two samples, Figures 92 through 97. The power spectra for these two samples shows a slope of approximately  $f^{-3}$  and  $f^{-2}$ , respectively, Figures 98 and 99. The 15 June fading showed an  $S_4$  Index of only 0.2, while the 16 August fading exhibited an  $S_4$  Index of 0.25.

Observations of data from the DNA-002 satellite by Rino, et al (Reference 8) in Alaska showed both amplitude and phase scintillation occurring regularly throughout the year. One unexpected result was the occurrence of significant phase scintillation under conditions of very weak amplitude scintillations in the auroral oval. A sample of Rino's measurements is shown in Figure 100. Rino concluded that the phase scintillation in the Polar region appeared to be stronger than phase scintillation associated with a similar amplitude scintillation in the equatorial region. Rino noted a geometric effect in that the scintillation appeared to be strongest when looking along a constant "L" shell. This would indicate that the irregularities are aligned along the magnetic line field lines and a greater thickness of irregularity results from looking along the field line.

#### SECTION IV

#### MIDLATITUDE SCINTILLATION CHARACTERISTICS

The occurrence of ionospheric scintillation in the midlatitude region is relatively rare. Occasional fades of several dB peak-to-peak at a 300 MHz frequency are occasionally observed in the midlatitudes, Mass and Houminer (Reference 20). Fades caused by a single ionospheric irregularity also occur, as reported by Slack (Reference 21). These irregularities cause a ringing type defraction pattern which Slack refers to as "Quasi periodic amplitude scintillation", Figure 101. However, since the occurrence of the scintillation is rare and the amplitude is small, midlatitude ionospheric scintillation is not expected to cause any significant outage to an aircraft-to-satellite communication system.

Figure 101. Examples of Ringing Irregularities (From Slack Reference 21)

## SECTION V

## ARTIFICIALLY DISTURBED IONOSPHERIC SCINTILLATION

During 1976 and 1977 a series of ionospheric scintillation tests occurred in which the ionosphere was artificially disturbed by the injection of 38 kilograms of a barium compound. The purpose of the test was to observe the effects of a carefully controlled ionospheric disturbance to learn more about the development of the irregularities and their late-time dissipation mechanisms. The barium injection occurred near Eglin AFB, Florida. A rocket launched to an altitude of approximately 180 kilometers released the barium which was ionized by the sunlight. The ions then flowed along the magnetic field lines as depicted in Figure 102. As the neutral ionospheric winds moved the barium ions across the local magnetic field lines, the magnetic field confinement force tended to cause the ions to bunch up or form a "hard edge" on the downwind side of the cloud. As this drift continued, the cloud broke up into a series of sheets or rods of irregularities, resulting in a striated structure, Figure 103. The striated structure is followed by a thin plasma sheet containing a uniform ion density shown in Figure 104. In the photograph of the irregularity structure shown in Figure 105, the color is caused by the reflection of sunlight shining on the irregularity cloud. Striations as narrow as a few hundred meters were observed during the test.

The test concept involved a test aircraft flying in the shadow of the cloud, communicating through the cloud to the satellite and back down. The usual flight path was perpendicular to the striations in such a manner that rapid fading would be experienced as the aircraft cut through various striated structures. Occasional flights along the striation were made to investigate the slow fading structure which would be encountered. Ground track of the aircraft for one of the tests is shown in Figure 106. The barium cloud tended to drift to the southeast, requiring the aircraft to move in that direction in order to stay in the shadow of the cloud. The wide portion of the ground track indicates areas where scintillation fading was encountered. Immediately after

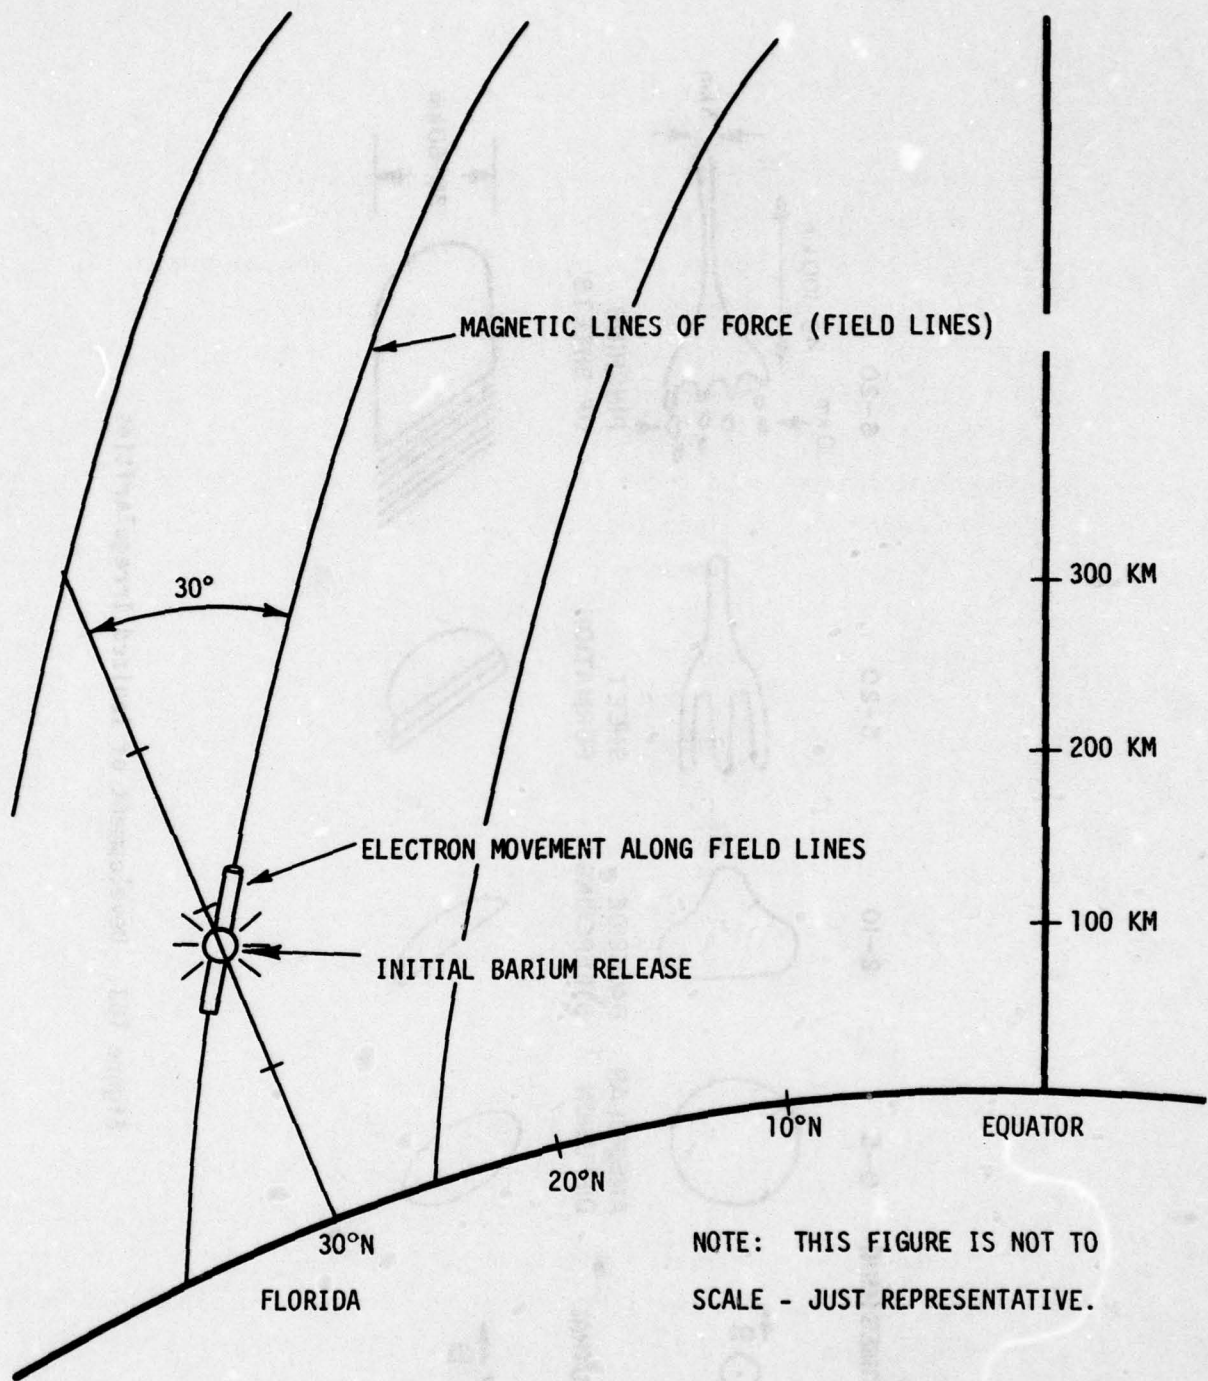

Figure 102. Propagation of Free Electrons Along Field Lines

Figure 104. Movement of Barium Ion Cloud

Figure 105. Photograph of Barium Ion Cloud

Figure 106. Plot of Aircraft Ground Track During Test Flight

the injection of the barium cloud the received signal amplitude variations shown in Figure 107, were experienced. Since the cloud was still in a spherical or cylindrical shape, the resultant scintillation was a single enhancement with a long, shallow fade followed by another enhancement at the end. The phase associated with this amplitude scintillation is shown in Figure 108. It was simply a smooth buildup of total electron content. As the hard edge and striations started developing amplitude scintillation, as shown in Figure 109, was recorded. At that time approximately 10 seconds of rapid scintillation was experienced followed by a shallow long fade with an enhancement at the end. The phase scintillation in Figure 110 (Reference 22) shows some sharp discontinuities on the leading edge with a smooth total electron content phase buildup. As the scintillation becomes fully developed, Figure 111, fades of 30 dB with 5 to 8 dB enhancements were experienced over the entire 30 second pass. The phase scintillation associated with this amplitude scintillation shows a bit more irregularity with phase changes of 5 to 10 radians per second on occasion, Figure 112. Histograms of the fade amplitude and accumulative distribution plots shown in Figures 113 to 114 approximate equatorial ionospheric scintillation. The auto correlation and power spectra, shown in Figures 115 and 116, appear quite similar to equatorial ionospheric scintillation. Plots of the fading duration and period are shown in Figures 117 and 118.

The fading expected from a single irregularity was simulated and is shown in Figure 119, Prettie, Reference 22. The amplitude and phase plots of a pass through the barium cloud closely resemble the simulated single irregularity plot as can be seen from Figures 120 and 121, along with their expansions, Figures 122 and 123. The ringing fade identified by Slack (Reference 21) as a quasi-period amplitude scintillation was observed during the barium cloud test. The deep amplitude scintillation exhibited in Figure 124 shows a ringing at the end, indicating the hard edge of the barium cloud. The phase associated with that plot is shown in Figure 125. The amplitude data at the end of that trace has been expanded and is shown in Figure 126 with the expanded phase in Figure 127.

Measurements through the barium cloud of two frequencies separated by approximately 90 MHz resulted in a cross correlation shown in Figure 128. This cross correlation indicates that a frequency separation of 90 MHz is sufficient to almost completely decorrelate the fading of the two signals.

## SECTION VI

## CORRELATION WITH OTHER PHENOMENA

Ionospheric scintillation fading can be correlated with measurement techniques other than direct satellite signal measurements. One technique is the use of a backscatter radar such as the Jicamarca, Peru 50 MHz radar. The Jicamarca radar can map the small scale irregularity (3 meter scale size) from the electrojet up to 1000 kilometers or higher. Jicamarca utilizes over 9000 antenna elements and a high peak pulse power to measure the small irregularities. A plot of the radar return is shown in Figure 129 for March 1977. The plot was made with data furnished by Dr. Phil McClure, University of Texas. The top panel of Figure 129 shows a strong irregularities occurring between 200 and 350 kilometer altitude at 1940 local time. That irregularity structure was observed for approximately one hour. After an hour of negligible activity another irregularity structure drifted by with a strong structure at the 300 kilometer minimum altitude and a plume extending up to approximately 1000 kilometers. The scintillation fading observed on an aircraft-to-satellite link passing through the 300 kilometer altitude volume over Jicamarca is shown in the bottom panel of Figure 129. The scintillation data correlates very well with the three meter scale size irregularity observations. This does not mean, however, that the three meter scale size is causing the aircraft-to-satellite fading. It indicates that the kilometer scale size irregularities which do cause UHF scintillation fading are co-located with the three meter irregularities.

Another technique for observing ionospheric irregularities is the use of an HF sounder as used for example on-board the Air Force Geophysics Laboratory's Airborne Ionospheric Observatory. Reflections from the irregularities indicate the base of the irregularities height and can be used to map the horizontal extent of the irregularity structure. The plots in Figure 130 from Buchau, et al (Reference 23) describe the state of the ionosphere prior to, during, and following the occurrence of irregularities. The ionogram of 0204 Universal time (UT) shows a

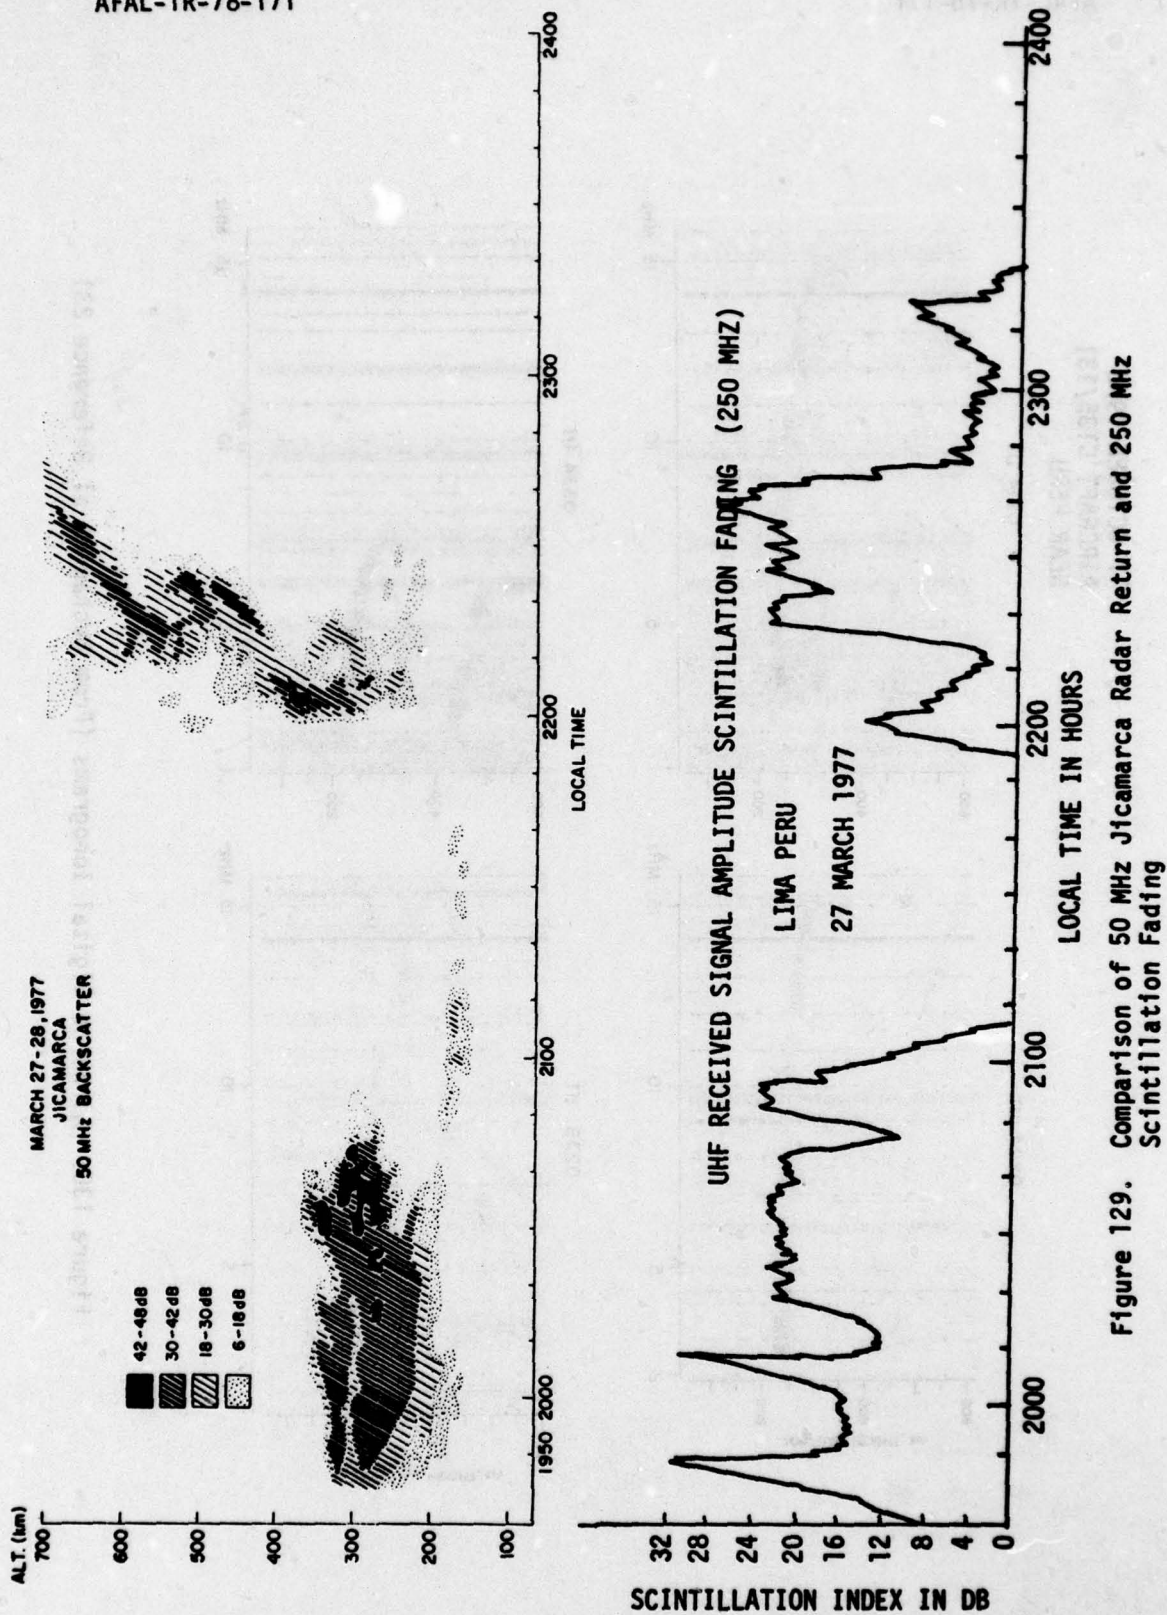

Figure 129. Comparison of 50 MHz Jicamarca Radar Return and 250 MHz Scintillation Fading

17 OCTOBER 1976  
AIRCRAFT C135/131  
NEAR PERU

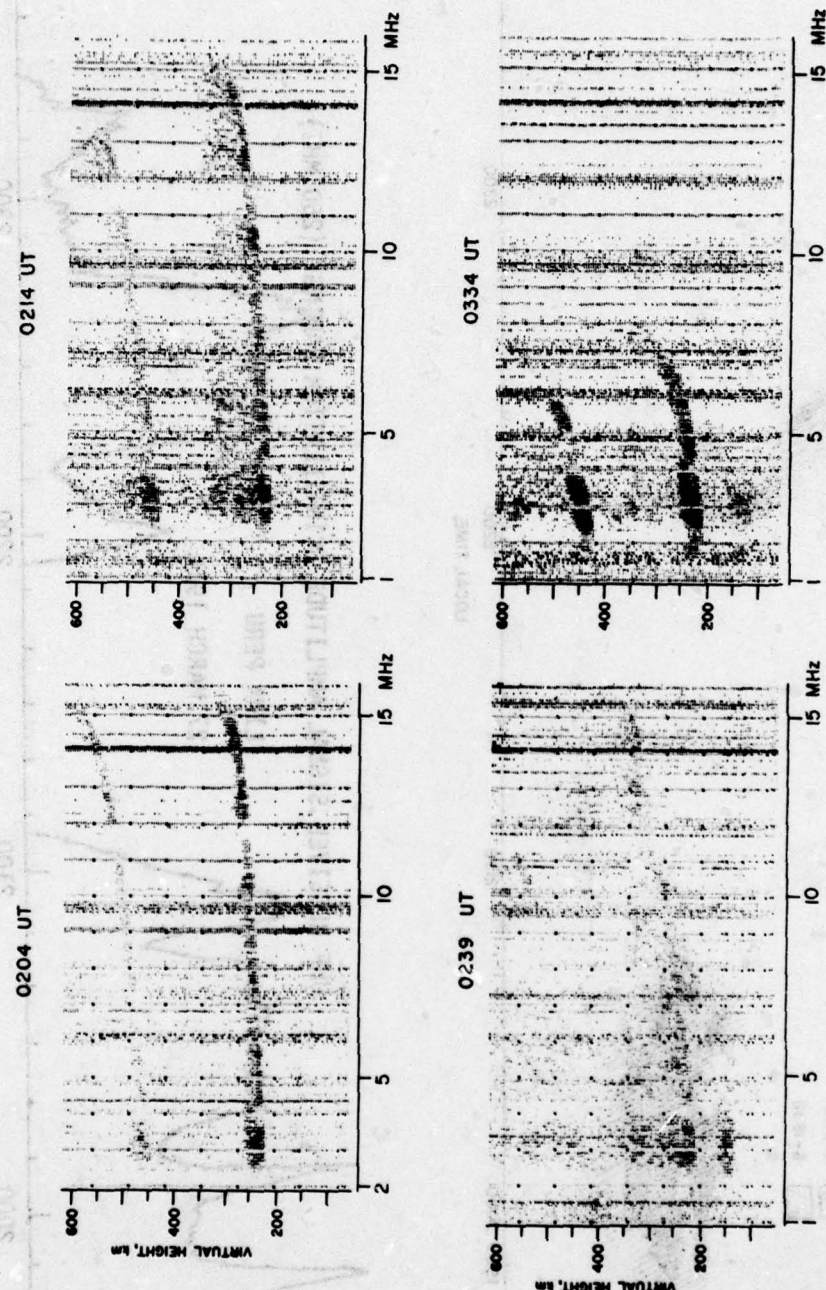

Figure 130. Airborne Digital Ionograms (From Buchau et al Reference 23)

typical night time ionosphere. The narrowness of the traces indicates a well-defined smooth F layer and the absence of irregularities. The 0214 UT frame shows a typical spread F ionogram, indicating the presence of F region irregularities. These irregularities appeared simultaneously with the onset of deep UHF scintillation fading observed on a ray path through this ionosphere. The echoes observed at 0239 UT show strong spread F and a well-defined oblique trace in the spread, indicating the presence of a large scale irregularity. The final ionogram at 0234 UT indicates the restoration of quiet ionospheric conditions with the absence of irregularities. The UHF scintillation fading quit as the ionosphere approached its undisturbed state.

A new observation technique being used by the Air Force Geophysics Laboratory is the large scale mapping of the 6300 Å air glow emission with an airborne imaging all sky photometer. The 6300 Å emission is a measure of the electron content of the lower F region. Any structure in the lower F region is thus observable as a structure in the airglow images. The results shown in Figure 131 from Weber et al (Reference 15) show a depletion region extending from horizon to horizon in the north-south direction, moving in a westerly to easterly direction. The airglow depletion region first appears on the western horizon around 0200 UT. It moves to an overhead position around 0330 UT. The depletion region had dimensions of at least 1200 kilometers north-south by approximately 165 kilometers east-west. The region was traveling at a velocity of 92 m/sec, reaching the eastern horizon around 0430 UT. This depletion region correlated with the Jicamarca backscatter and observed UHF scintillation fading Buchau et al (Reference 24).

## SECTION VII

### MITIGATION TECHNIQUES

The obvious mitigation techniques such as avoiding the scintillation region or providing sufficient link margin to overcome the scintillation often do not prove to be practical. Antenna diversity with antennas spaced up to a kilometer apart has been shown to be extremely effective by Naval Ocean Systems Center (NOSC), Paulson and Hopkins (Reference 6). By utilizing a predetection combiner, the error rate during a scintillation period was reduced from an unacceptable  $10^{-2}$  to an undetectable error rate. Unfortunately for airborne applications antenna spacings of greater than 30 meters are not practical. Therefore, the antenna diversity, or antenna spacing technique, remains applicable primarily to ground systems.

Sufficient frequency separation accompanied by some type of combining technique will provide adequate performance in a scintillation fading environment. Measurements by Fremouw of the DNA 002 satellite et al (Reference 8) and by Prettie et al (Reference 22) during the barium cloud experiment showed that at UHF frequencies decorrelation can occur with 50 to 100 MHz signal separation.

The use of message interleaving and error correction coding or time diversity appears to be a very practical mitigation technique. The results of the Air Force Avionics Laboratory's (AFAL) fade resistant modem test, Fischbach (Reference 25) and Air Force Weapons Laboratory (AFWL) simulations, Wittwer (Reference 26), show that interleaving and coding can significantly improve the performance of the communications system. The interleaving and coding technique should be tailored to the fade rate and fade duration expected to optimize the message throughput.

The use of satellite diversity, two satellites relaying the same message, can successfully overcome the effect of the scintillation fading. Cross correlation plots of the two UHF satellites taken during the Peru Test (Figure 132) showed a correlation coefficient of 0.1 or

Figure 132. Cross Correlation Function of Received Signal Amplitude on Two UHF Satellites

less was achieved. The ionospheric intersection points for this example were separated by more than 300 kilometers. Some type of combining or switching would be required to utilize the unfaded signal.

Another technique which has been suggested for mitigating the effect of the fading is to use a path diversity to the satellite by utilizing the multipath situation available to an airborne receiver. As shown in Figure 133, one path would be the direct path to an antenna on top of the aircraft, while a second path would be via a multipath reflection off of the earth's surface to antenna on the bottom of the aircraft. These two signal paths are sufficiently separated as they traverse the ionosphere to make any ionospheric fading they encounter uncorrelated. Therefore, the combination of the signal received on the top and bottom of the aircraft can significantly improve the system performance.

Figure 133. Geometry of Fade Mitigation Technique

A simulation of the technique, done by Prettie, indicates that moderate improvements can be achieved for an interleaved, encoded signal, and significant improvement can be achieved for an uncoded FSK signal using the multipath technique. Tests of the multipath bounce technique are planned for late 1978 by AFAL and ESL.

## CONCLUSIONS

Ionospheric scintillation fading in the equatorial regions has a strong seasonal dependence. In some equatorial areas, such as Peru, the fading peaks during the two equinox periods. In other areas, such as the western Pacific, the fading appears to peak during the local summer period. The equatorial fading is, in general, limited to a region of  $\pm 20^\circ$  from the magnetic equator. The fading is generally extremely deep when it does occur. Data taken by AFGL indicates that 25 dB fades are just as likely to be encountered as 5 dB fades, Figure 134. The onset of fading usually occurs 1 to 2 hours after local sunset. Fading may occur sporadically over the next 4 to 5 hour period. An aircraft may experience fade rates from one fade per second to as low as one fade in 90 seconds. The corresponding duration of the fade is from a tenth of a second to 10 or 15 seconds, depending upon aircraft flight direction. The amplitude of equatorial fading is frequency dependent with a dependence of approximately  $f^{-2}$ . The phase scintillation which accompanies the amplitude scintillation does not appear to be rapid enough to affect moderate data rate phase modulated communication systems.

In the Polar region an airborne terminal can be expected to encounter scintillation more often but with less amplitude than in the equatorial region. Scintillation at Ultra High Frequencies is often encountered during the daylight hours in the Polar region but almost never in the equatorial region. Fade rates of one cycle in five seconds to one cycle in 30 seconds may be experienced. Amplitude fading depths of 5 to 10 dB can be expected. Slightly stronger phase scintillation may be experienced in the Polar region, but this phase scintillation still appears to offer no problem to a moderate data rate phase modulated communication signal.

Interleaving, coding on a multipath bounce mitigation techniques can greatly improve system performance during ionospheric scintillation fading in the Equatorial or Polar regions. However, due to the smaller fading amplitude in the Polar region, it may be more economical to just

Figure 134. Histogram of Scintillation Index Levels for Ancon Peru  
(From Whitney et al Reference 14)

increase the system fade margin to 10 dB which will significantly reduce the fading problem in the Polar region.

Fading in the midlatitude region occurs very seldom and, when observed, is usually weak. Therefore, the effect of ionospheric scintillation fading in midlatitudes is expected to be small when compared with other airborne satellite communication system problems such as antenna blockage and multipath fading.
